Splines, model complexity, and prediction error

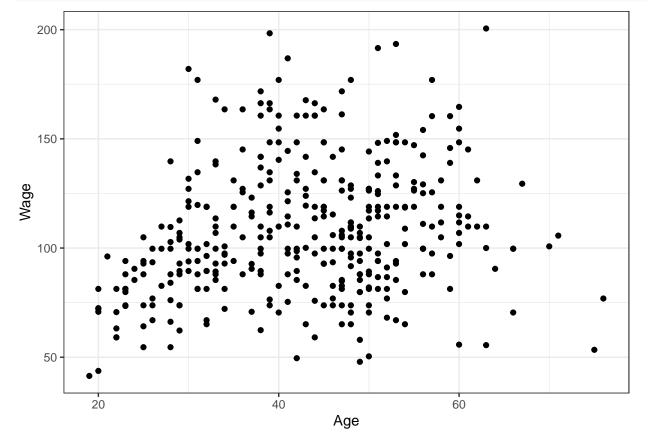

September 16, 2021

Fitting, predicting, and plotting with splines

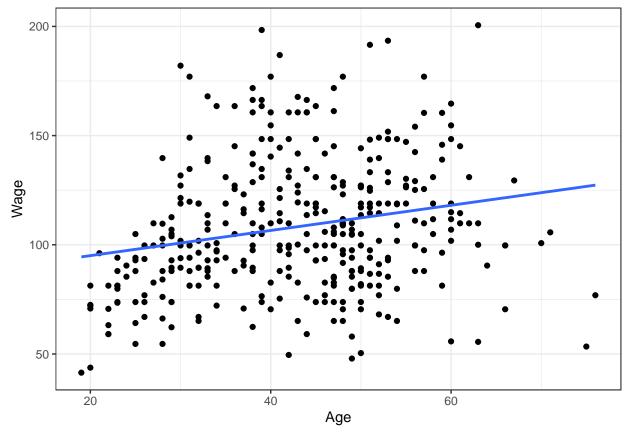

Let's first see how some of the plots from the lecture slides were generated. These plots are based on the Wage data from the ISLR2 package, which accompanies the ISLRv2 course textbook.

```
Wage = ISLR2::Wage %>%
  as_tibble() %>%
  filter(wage < 225) # remove some outliers</pre>
```

Extract data from 2007:

We can add the least squares line to these data using geom_smooth():

Fitting a spline is almost as simple as fitting a linear regression, since since a spline fit is after all a regression fit! We can use the following syntax:

```
spline_fit = lm(wage ~ splines::ns(age, df = 5), data = Wage_2007)
```

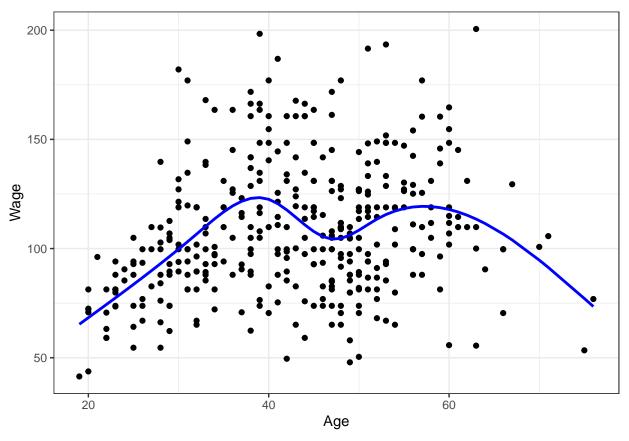

Typically we inspect the results of a regression using summary():

```
summary(spline_fit)
```

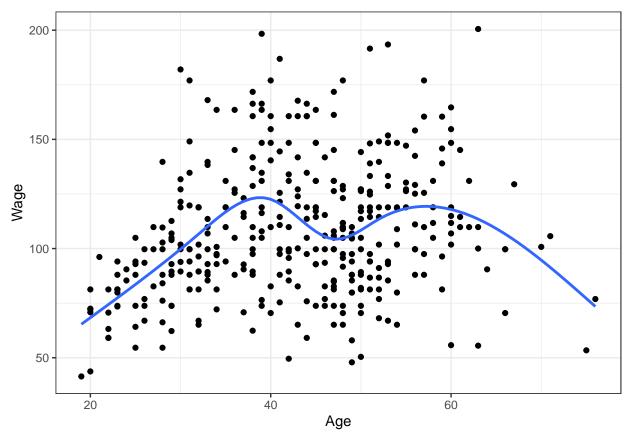

```
##
## Call:
## lm(formula = wage ~ splines::ns(age, df = 5), data = Wage_2007)
##
## Residuals:
## Min 1Q Median 3Q Max
## -68.134 -19.344 -0.782 15.851 87.041
##
```

```
## Coefficients:
                            Estimate Std. Error t value Pr(>|t|)
##
## (Intercept)
                             65.348
                                         8.230 7.940 2.44e-14 ***
## splines::ns(age, df = 5)1
                             69.939
                                         8.783
                                                 7.963 2.08e-14 ***
## splines::ns(age, df = 5)2 29.958
                                        10.006
                                                 2.994 0.00294 **
## splines::ns(age, df = 5)3
                            59.448
                                         8.904
                                                 6.677 8.96e-11 ***
## splines::ns(age, df = 5)4
                             67.113

                                                 3.242 0.00130 **
## splines::ns(age, df = 5)5
                                        15.051 -0.539 0.59022
                             -8.112
## Signif. codes: 0 '***' 0.001 '**' 0.05 '.' 0.1 ' ' 1
## Residual standard error: 27.74 on 370 degrees of freedom
## Multiple R-squared: 0.1746, Adjusted R-squared: 0.1634
## F-statistic: 15.65 on 5 and 370 DF, p-value: 5.583e-14
```

Actually in this case, we're less interested in the coefficients (or p-values) of the linear regression and more interested in the fitted function. We can extract the fitted values and add them to the plot as follows:

There's actually a simpler way of making the same plot via <code>geom_smooth()</code>, just substituting a different <code>formula</code> argument!

Now, in order to make predictions for a test dataset (e.g. the data from the year 2008), we can use the convenient predict() function.

```
Wage_2008 = Wage %>% filter(year == 2008)
predictions = predict(spline_fit, newdata = Wage_2008)
head(predictions)

## 1 2 3 4 5 6
## 117.17964 99.72272 119.32551 110.16106 113.49437 91.36378
length(predictions)
```

[1] 377

We can then add these predictions back to the data frame and compute the (root) mean squared test error:

```
Wage_2008 = Wage_2008 %>% mutate(prediction = predictions)
Wage_2008
```

```
## # A tibble: 377 x 12

    60 -
                    50
                                         100
                                                               150
                                                                                      200
                                              wage
Wage_2008 %>%
  summarise(test_error = sqrt(mean((wage-prediction)^2)))
## # A tibble: 1 x 1
##
     test_error
##
          <dbl>
## 1
           31.6
By contrast, let's take a look at the RMS training error:
Wage_2007 = Wage_2007 %>%
  mutate(fitted_value = spline_fit$fitted.values)
Wage_2007 %>%
  summarise(training_error = sqrt(mean((wage-fitted_value)^2)))
## # A tibble: 1 x 1
     training error
##
              <dbl>
```

1

27.5

Now, let's calculate the training and test errors for df = 1,2,3,4,5:

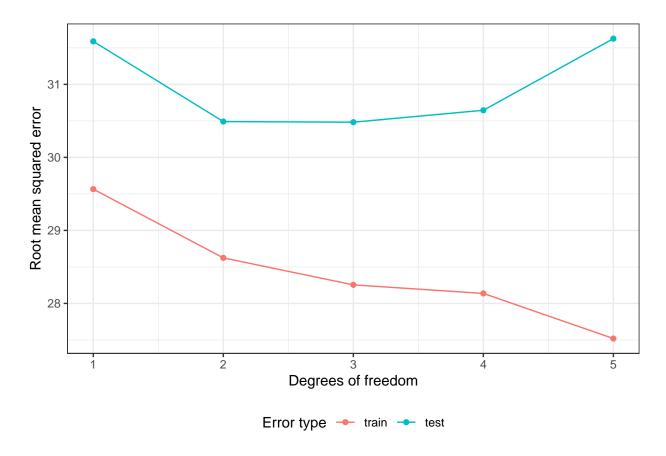

Let's take a look at these errors:

```
train_errors
```

```
## [1] 29.56470 28.62369 28.25417 28.13682 27.51901 test_errors
```

[1] 31.58897 30.49050 30.48212 30.64534 31.62660

Now let's plot them:

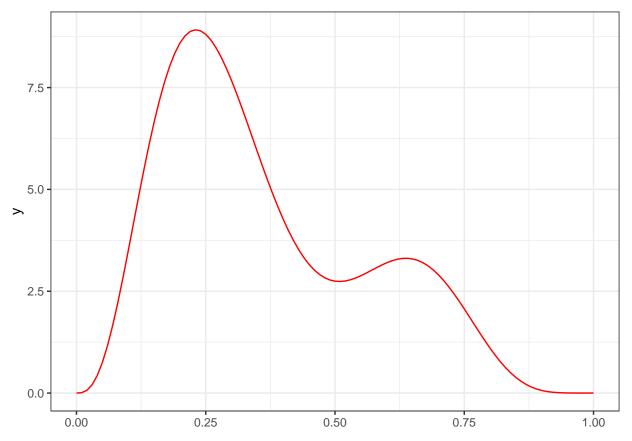

Exercise: Exploring model complexity in a simulation

In the Wage data, we don't know what the "true" trend is. It may be illuminating, therefore, to replace this data with *simulated* data (i.e. data we generate ourselves). Suppose that $Y = f(X) + \epsilon$, and let us assume f take the following form:

```
# credit: this function comes from
# https://gist.github.com/rudeboybert/752f7aa1e42faa2174822dd29bfaf959
f <- function(x){
    0.2*x^11*(10*(1-x))^6+10*(10*x)^3*(1-x)^10
}</pre>
```

It's hard to understand what this function is but we can plot it:

```
ggplot() +
  stat_function(fun = f, colour = "red") +
  theme_bw()
```

- 1. Create 500 training data points (X,Y) as follows. First, generate 500 equally spaced values of x between 0 and 1 (using the seq function). Then, sample a vector y based on $Y = f(X) + \epsilon$, where $\epsilon \sim N(0, \sigma^2)$ and $\sigma = 2$. Put x and y into a tibble called data.
- 2. Create a scatter plot of these data, overlaying the function f in red.
- 3. Take a look at what natural spline fits look like for this data, using different degrees of freedom. Using <code>geom_smooth()</code>, plot natural spline fits with degrees of freedom equal to 2,10,25,50 (use separate plots for each value of df). For each of these plots, superimpose the true trend as a red line. Comment on what happens as you increase the degrees of freedom. Which of these four values seems to fit the scatter plot best?
- 4. (If time permits) Create a test data set with 500 additional points from the same distribution and compute the root mean square test error for each of the four spline fits above. Does the degrees of freedom that gives the closest fit to the underlying trend also lead to the lowest test error?
